Abstract:

**Background:** Global longitudinal strain (GLS) echocardiography is a new technique that can be used to detect an early left ventricular dysfunction in various heart diseases. Systemic hypertension is a major risk factor for cardiovascular accidents. The early management of its complication on the heart plays an important role in the outcome of the disease. Hypertension is associated with changes in several aspects of left ventricular structure, function, and systolic strains. Various echocardiographic techniques are used to evaluate left ventricular function in hypertensive patients.

**Objectives:** To evaluate the effectiveness of speckle tracking global left ventricular strain percentage (GLVS%) in the assessment of left ventricular systolic function in comparison to conventional echocardiography in middle-aged hypertensive patients.

**Patients and Methods:** The study was conducted from December 2017 till November 2018 at the Department of Echocardiography and Catheterization / Baghdad Teaching Hospital – Medical City, Baghdad, Iraq. One hundred and four hypertensive patients classified as: group I that involved patients with reversed E/A ratio on PW Doppler with reversed Pulsed Wave (PW) tissue Doppler study and group II with patients having normal E/A ratio on PW Doppler and reversed E prime/A prime on PW tissue Doppler study. The control (group III) recruited from the relative of the patients included 104 sex and age-matched healthy individuals. A detailed history with the recommended investigations and blood pressure measurements was performed for all participants. Additionally, echocardiography examination was implemented using standard methods, considering left ventricle (LV) internal dimension, LV ejection fraction percentage (LV EF%), LV diastolic function using PW Doppler and lateral mitral annular tissue Doppler, S prime, Mitral annular plane systolic excursion (MAPSE) and global LV speckle tracking strain percentage (GLVS%).

**Results:** Group I included 76 patients with a mean age of (48 ± 6.6 years) and group II included 28 patients with a mean age of (48 ± 6.6 years). All the participants had normal EF% (> 60%), MAPSE (>13 mm), and S prime (>9 cm/sec) while there were a significantly decreased GLVS% in the diseased groups in comparison to the control one (P < 0.005) being less in group II (-14 ± 1%) than in group I (-16 ± 1%). In addition to a significant negative linear correlation between GLVS% with that of pulse pressure and IVST respectively (p=0.04) and with that of E/A ratio and E/E prime ratio (p=0.001).

**Conclusions:** GLVS% is a better method in the assessment of LV systolic function in middle-aged hypertensive patients than conventional echo methods since it could detect an early impairment in LV systolic function despite preserved LV systolic function measured by the conventional echo methods.

**Keywords:** Systemic hypertension; Tissue Doppler Imaging; Speckle tracking echocardiography.

**Introduction:**

Hypertension is a major risk factor for cardiovascular diseases with high morbidity and mortality as it increases the heart work (1, 2).

Systemic pressure overload causes different changes in longitudinal, radial and circumferential mechanics of the heart (3). In addition to mechanical changes, systolic and diastolic functions are significantly affected in patients with systemic hypertension (4). Echocardiography is a non-invasive most widely used diagnostic test in cardiology, which is also safe and accurate in the diagnosis of cardiac diseases in all ages even in pregnant and fetal life (1, 5). Although echocardiography is a second-line study in the evaluation of hypertensive patients, it is a valuable, easily reproducible tool to give clue impression about...
LV geometry, systolic and diastolic changes. Left ventricular ejection fraction percentage (LV EF%) represents the global result of both longitudinal and circumferential contraction; it provides only an indirect estimate of myocardial contractile function and does not measure it directly. Second, it is readily influenced by a number of factors including loading conditions, heart rate, etc. Third, and the most important, it is not sensitive enough to detect subtle changes in the contractile function and therefore not suitable for detecting subclinical myocardial damage (1). Mitral annular plane systolic excursion (MAPSE) has been suggested as a parameter for left ventricular (LV) systolic function which reflects LV longitudinal function and thus provides complementary information to EF%. Moreover, reduced MAPSE could be used as a sensitive early marker of LV systolic dysfunction in hypertensive patients with normal EF, where compensatory increased circumferential deformation might mask the reduced longitudinal deformation (6).

In Tissue Doppler Imaging (TDI) the S prime velocity waveforms which correspond to the peak systolic contraction velocity correlates well with global LV function even though it is very much preload-dependent (7). Echocardiographic strain imaging is an innovative approach recently developed for the assessment of LV myocardial mechanics, an angle-independent technique, because it tracks deformation between acoustic markers in the ultrasonic image in two dimensions and employs automated algorithms to analyze temporal variations (frame to frame) in the mobility of acoustic speckle markers of 20-40 pixels’ size along different spatial orientations. Strain is the percentage change in the length of a myocardial segment during a given period of time and has a unit of %. As the myocardium shortens during systole, the strain has a negative value but when there is stretch or lengthening of the myocardium, the strain becomes positive. The gray-scale image on echocardiography is composed of several bright speckles that are produced as a result of the scatter of the ultrasound beam by the tissue. The STE software identifies these speckles and then tracks them frame-by-frame using a ‘sum-of-the absolute differences’ algorithm. From this data, the software automatically resolves the magnitude of myocardial deformation in different directions and generates strain (8, 9). This study aimed to Correlate the effectiveness of speckle tracking echocardiography using global left ventricular strain percentage (GLVS%) with the conventional echocardiography in the assessments of LV systolic function in middle-aged hypertensive patients.

**Patients and Methods:**
This study was performed from December 2017 till November 2018 at the Department of Echocardiography and Catheterization / Baghdad Teaching Hospital – Medical City, Baghdad, Iraq. One hundred and four patients with essential (primary) hypertension with an age range from 35 to 55 years of both sexes were included. These patients were categorized into two groups; group I patients on Pulsed Wave Doppler (PWD) with reversed E/A ratio and reversed Eprime/Aprime ratio on PW tissue Doppler image (TDI), and group II patients with normal E/A ratio on PWD and reversed Eprime / Aprime ratio on PW by TDI. One hundred and four sex and age-matched healthy individuals were recruited from the relative of the patients as a control group III. Patients with ischemic heart disease, diabetes mellitus, renal failure, primary pulmonary disease, valvular heart diseases, thyroid diseases, hyperlipidemia, SLE, atrial fibrillation, obesity, cardiomyopathy, infiltrative cardiac disease, current and history of heavy smoking and those with poor quality echocardiographic images were excluded. All individuals received written information and gave informed consent. Medical history, ECG, CXR, investigations that are required to exclude the diseases in the exclusion criteria were done. Measurements and calculation of BMI and BSA. Blood pressure were taken according to the American College of Cardiology (ACC) and American Heart Association (AHA) guideline for blood pressure measurements (10) using Rossmax MG150f Digital sphygmomanometer.

Echocardiography was done including standard 2-D and Doppler studies according to standardized protocol of American Society of Echocardiography (ASE) and the European Association of Echocardiography recommendations 2015 using a 3.5 MHz transducer with available equipment (Philips CX 50 ultrasound, USA machine). The Interventricular septum (IVSd) and left ventricle posterior wall measurements were calculated from the standard left parasternal long axis view at the end of diastole. Left ventricle (LV) internal dimension during systole and diastole were carefully obtained in the 2D-guided M-mode echocardiography then according to the Teichholz M-mode formula the LV ejection fraction % was calculated by the machine software as shown in figure 1(11, 12).

![Figure 1: M-mode guided by 2-D echocardiography for LV EF% calculation.](image-url)
LV mass index (LVMI) and Relative wall thickness (RWT) were then calculated. LV geometry was classified according to the presence or absence of LV hypertrophy defined by an LVM index as accepted by the ASE and the European Association of Cardiovascular classification (13). Mitral annular plane systolic excursion (MAPSE) was measured in the M-mode while the cursor was placed to the junction of mitral valve (MV) plane with the free wall of the left ventricle (LV) as shown in figure 2 (14).

Figure 2: Mitral annular plane systolic excursion measurement.

Transmitral PWD was obtained at the mitral leaflet tips, the peak early (E), late (A) diastolic filling velocities and E/A ratio were recorded (15), TDI with the PWD sample volume placed at the lateral mitral annulus was used to measure the initial first negative (E prime) and a late positive (S prime) wave velocities as shown in figure 3 (16).

Figure 3: PW tissue Doppler imaging for measuring S prime velocity. Additionally, LV Speckle-tracking echocardiography was obtained from apical four, three and two-chamber views during stable ECG recording and end-expiratory breath-hold using an offline QLAB-CMQ software program (17). The three-point-and-click method used manually adjustments the region of interest was then done. After that, the software divides the LV myocardium into six parts and generates global longitudinal strain calculated for each view then the global Bull’s eye shows an 8-segmental model with averaged global longitudinal strain %. However, the average of three consecutive cardiac cycles was recorded as a strain value as shown in figures 4 and 5 (18).

Figure 4: Global LV Strain in 4-chamber view.

Figure 5: Global longitudinal LV Strain %.

Statistical Analysis:
In this case-control study, data was analyzed using SPSS version 20 for windows. For all tests, a probability value (P-value) of ≤0.05 was considered to be statistically significant. Normally distributed data were presented as mean ± SD for continuous variables. Statistical comparisons among more than two groups were carried out by one-way analysis of variance (ANOVA). Pearson’s correlation coefficient (r) was used to test the correlation.

Results:
The studied sample with a mean age of 48± 6.6 years was categorized into three groups according to Doppler studies as:
Group I: Included 76 (73 %) systemic hypertensive patients of either sex; 44 women and 32 men with reversed E/A ratio on PW Doppler and reversed E prime /A prime ratio on PW tissue Doppler with a mean age of 48.41± 6.36 years.
Group II: Included 28 (27%) systemic hypertensive patients of either sex; 17 women and 11 men with normal A ratio on PW Doppler and reversed E
prime/A prime ratio on PW tissue Doppler with a
mean age of 49.38 ± 5.32 years.
Group III: Included 104 healthy subjects of either sex;
41 men and 63 women with normal Doppler study
served as a control group with a mean age of 48.92 ± 6.03 years.

The characteristics and demographic data of the
studied groups are shown in Table 1, which
demonstrates that they were age, BMI and BSA
matched groups (P > 0.05).

Table 2 shows that there was a significant
difference between the diseased groups regarding the duration of
hypertension ((P = 0.005) with a longer disease
duration in Group II (9.5 ± 4.23 years) while it was
(6.5 ± 4years) in Group I. There was a higher percentage
of uncontrolled hypertension in Group II
(89.1%) than in Group I (69.7%). A significant
difference was found between the studied groups in
respect to their systolic blood pressure and pulse
pressure being higher in group II with mean systolic
blood pressure of (158 ± 15) mmHg and a mean pulse
pressure of (69 ± 10) mmHg. However, the diastolic
blood pressure results show a significant difference
between the diseased and the control groups, with the
mean reported in group II (89±9) mmHg.

Table 3 demonstrates a significant difference (P < 0.05) between all groups regarding IVST, PWT, and
RWT being the largest thickness in Group II. While
there was a significant difference (P < 0.05) in the LV
internal dimensions and volumes (LVIDd, LVIDs, and LVEDV) with the least volume reported
in group II (105±28 ml). The largest mass index was
found in the same group (group II). Moreover, LVH
was reported in all patients in Group II in addition to
a maximum septal thickness was recorded in group II
(1.2 ± 0.2 cm). LVH was reported only in (71%) of
patient in Group I. However, the only type of
geometrical changes in LV in both diseased groups
was of concentric hypertrophy.

Left Ventricular End Diastolic Volume and LVESV= Left Ventricular End Systolic Volume, RWT= Relative wall thickness, LVMI = Left Ventricular mass index, LVH= left ventricular hypertrophy.

Table 4 demonstrates the LV function. Regarding the diastolic LV function, the table validates that the peak E velocity was significantly decreased in the diseased groups being the least velocity in group I (72 ± 14) cm/sec while there was a significant decrease in the E prime velocity being the least velocity in group II (6.6 ± 1.19) cm/sec. In addition, there was a significant increase in the E/E prime ratio noticed in the diseased groups being the highest ratio in group II (15.3 ± 0.99). The table shows the LV systolic function to be within normal values in respect to conventional methods with the significant differences being between the diseased groups and the control one regarding left ventricle LV EF% being higher in group II (68 ± 9%). Furthermore, the S prime measurement shows no significant difference (P>0.05) between the studied groups with results recorded being more than 11 cm/sec in all groups. Moreover, regarding the last conventional method which was MAPSE measurement show that there was no significant difference (P>0.05) between the studied groups with results recorded being more than 12 mm in all studied groups. However, global LV speckle tracking measurement shows a significant difference (P<0.05) between the diseased groups in comparison to controls with the GLVS% being (-14 ± 1%) in group II and (-16 ± 1) in group I while it was (-21.9 ± 1) in the control group.

- LVESV% = Left ventricular Ejection Fraction percentage, MAPSE = Mitral annular plane systolic excursion and GLVS% = Global longitudinal ventricular strain percentage.

Linear regression using Person correlation shows a significant negative linear correlation between GLVS% with that of pulse pressure and IVST respectively (r = -0.25, p = 0.015) (r = -0.22, p = 0.04).

The results show a highly significant high negative linear correlation between GLVS% with the of E/A ratio and E/E prime ratio respectively (r = -0.629, p = 0.001) and (r = -0.62, p = 0.001).

Discussion:
The mean systolic and diastolic blood pressure values are in similar to those reported by Muataz et al. and Xu et al (2,19) but are higher than those of Maryam et al. being higher in this study (20). These differences may be related to that most of the patients in the current study are with uncontrolled blood pressure was (69.7% of group I and 89.1% of group II). The RWT is a marker of adverse hypertensive effect on the heart for a long-standing time (21). The estimated RWT of the LV in our study revealed that there was only concentric LVH was seen in all patients in group II and 71% of the patients in group I. This can be explained by the observation that those patients have the highest blood pressure that adversely affects cardiac structure and results in LVH which is a maladaptive response to chronic pressure overload. These results are in concordance with Elmasry et al. and Mizuguchi Y et al. (22, 23) but not in agreement with Izzo et al. (24) which found that all

Figure 1: Correlation between GLVS and E/E prime.

J Fac Med Baghdad 34 Vol.61, No.1, 2019
the patients developed LVH. This may be attributed to the younger age of our study group and the exclusion of those of with risk factors like diabetes mellitus, obesity, and coronary artery diseases. This current study revealed a normal LV systolic function measured by MAPSE and tissue Doppler by measuring S prime velocity. The slightly higher reading of EF% reported in group II (68± 9%) is in agreement with the studies of Sharief K. M. et al., Salam et al. and W.A.I. Hamed et al. (25,26, 27) in which the LVH might be attributed to the explanation of higher EF%.

Diastolic dysfunction can happen in hypertensive patients before systolic dysfunction, which may be due to a noncompliant hypertrophic LV even without obvious signs of heart failure (25, 28). Moreover, delayed LV relaxation with the resultant increased early diastolic pressure, and a reduced transmitral pressure gradient explains the reversed E/A ratio and normal TDI study in group I patients, while in group II patients, the results revealed a higher E velocity and E/E prime ratio due to further deterioration of diastolic function and impedance to atrial emptying. These differences in the LV diastolic function may be related to hypertension that affects LV compliance and decreases in relaxation of the LV. Additionally, the longer duration of hypertension that exacerbates the deterioration in the diastolic function where the duration of hypertension in group II is (9.5 ± 4 y) while in group I is (6.5±4y). This finding is in agreement with those of Vijaykumar, Ting-Yan Xu et al. and Shantanu et al. (29,19,30). Speckle Tracking Echocardiography is an imaging technique that is used to analyze the tissue motion in the heart by using the naturally occurring myocardial speckle pattern when imaged by ultrasound (31). In respect to global GLVS %, our results demonstrated a reduced global LV longitudinal strain which reflects early changes in systolic function in hypertensive patients being less in group II (-14 ± 1%) than to group I (~ 16± 1%). However, the global GLVS% was reduced despite the normal conventional echo parameters (EF%, MAPSE, and S prime measurements). This finding goes in parallel with those of W.Hamed et al. Amal et al. , Kraigher et al. Jun et al. and Minatoguchi S.et al. findings (27, 32, 33, 34, 35). Kraigher et al demonstrates lower GLVS% in heart failure with preserved EF% and in hypertensive patients compared to normal group whereas the others demonstrated impaired systolic function in hypertensive patients using GLVS% with normal EF%. Correlation analysis revealed a significant negative linear correlation between GLVS% with that of pulse pressure and IVST pulse pressure in addition to high negative linear correlations between GLVS% with that of E/A ratio and E/E prime ratio. This can be explained by increased pulse pressure, with the more hypertrophied ventricle with the resultant increased filling pressure of the LV leading to more deterioration in diastolic function with the resultant worsted GLVS%.

Global left ventricular strain percentage (GLV5%) is a better method in the assessment of LV systolic function in middle-aged hypertensive patients than conventional echo methods since it can detect an early impairment in LV systolic function despite preserved LV systolic function measured by the conventional echo methods.

The role of two-dimensional speckle tracking strain in assessing left ventricular systolic function in middle-aged hypertensive patients.

Abstract:
Background: Hypertension is one of the major risks to the heart and circulation. Early treatment of patients has a significant role in reducing complications that affect the left ventricular function.

Objectives: To evaluate left ventricular systolic function using two-dimensional speckle tracking strain compared to conventional echocardiography.

Methods: A study of 104 patients with hypertension, group 1 included 76 patients with low systolic function, while group 2 included 28 patients with moderate systolic function, and group 3 included 104 healthy individuals. The study included clinical examination, blood pressure measurement, and echocardiography for systolic and diastolic function of the left ventricle.

Results: The results showed that the systolic function of the left ventricle using tissue Doppler imaging (TDI) and short axis strain (S') was normal, while the strain ratio was significantly lower in group 1 (13.54 ± 1.5%) and group 2 (16.55 ± 1.4%). The correlation was significantly positive with systolic blood pressure and left ventricular mass index. The conclusion: Early detection of left ventricular systolic dysfunction using speckle tracking strain, especially the strain ratio, is important in early detection of hypertension.

Keywords: Hypertension, speckle tracking strain, tissue Doppler imaging.
